ABSTRACT
Lumbar puncture (LP) is a useful diagnostic tool in a wide spectrum of paediatric clinical situations. A common indication is to rule out a serious intracranial infection in a febrile child. Success rate can be optimised by proper positioning, appropriate technique and enhanced operator’s skill in performing the procedure. The purpose of this review is to explore the indications and contraindications for performing paediatric LP, to describe the anatomical and physiological knowledge required to maximise success rates and to describe complications and their management. We will also provide advice on requesting various cerebrospinal fluid studies, interpretation of results and clinical situations in which LP may be indicated.

INTRODUCTION
Worldwide, central nervous system infections in children are associated with significant morbidity and mortality. Early recognition and treatment is paramount for improving outcomes. Lumbar puncture (LP), the most common method for obtaining cerebrospinal fluid (CSF), has been employed for over a century to diagnose and aid the management of such infections. The role of LP now extends to diagnosing and treating a range of paediatric central nervous system disorders making it an essential skill for paediatricians to acquire.

Thomas Willis first described the role of CSF in disease in 1664 when he noted on postmortem examination of patients with ‘epidemic fever’ the consistency of the ‘liquid around the brain’ was turbid. In the 19th century, Francois Magendie hypothesised that CSF suspended, nourished and protected the brain and spinal cord. In 1891, Heinrich Quinke presented his technique for LP to the German Congress of Medicine. By 1912, CSF composition in health and disease was described by William Mestretaz providing the basis for the diagnostic use of LP.

PHYSIOLOGICAL AND ANATOMICAL BACKGROUND
CSF bathes, nourishes and protects the brain and spinal cord. The adult choroid plexus produces CSF at a rate of 14–36 mL/h; in neonates the rate is approximately 25 mL/day. Circulating CSF volume of a neonate is approximately 50 mL with this volume increasing with age until the adulthood volume of approximately 150 mL. CSF circulates through the ventricles, subarachnoid space, perivascular space and the central canal of the spinal cord and is reabsorbed into the bloodstream by arachnoid villi in the superior sagittal venous sinus. CSF and serum differ most dramatically in their protein concentration; in the healthy state CSF protein content is negligible. The blood-CSF barrier maintains this difference. In neonates, however, CSF protein concentration is higher due to immaturity of the blood-CSF barrier. Moreover, a value of up to 10 white cells/mm³ in the CSF is generally accepted in neonates.

The lumbar region is the safest location from which to sample CSF. Here, there is a large CSF-filled space containing only nerve roots, as the spinal cord terminates around the level of L1–L2, whereas the subarachnoid space extends to the lower border of S2 (figure 1). In neonates, the spinal cord reaches L3. LP should therefore be attempted between L3–L4 or L4–L5 to avoid trauma to the spinal cord. The anatomical layers pierced during LP are shown in figure 1.

TECHNICAL BACKGROUND
Prior to the procedure discussion with parents, and the child if appropriate, is important. They should be informed of
the indications, complications and how the procedure is performed. Consideration should be given to the use of sedation, local anaesthesia and analgesia. Conscious sedation (often with a benzodiazepine such as midazolam) is safe and effective in reducing parental and patient anxiety and reducing procedural pain. Self-administered nitrous oxide and oxygen mixture can also be helpful in the cooperative child. Topical anaesthetic agents such as eutectic mixture of local anaesthetic (EMLA) cream or tetracaine 4% (Ametop) gel should be used. EMLA is effective in significantly reducing pain in neonates. In paediatric practice, bevelled 22-gauge Quincke spinal needles are commonly used. Distance from skin to subarachnoid space increases with weight and is estimated using the formula: Depth (in millimetres) = 0.4 × weight + 20. Use of a non-stylet needle should be avoided for concern that skin epithelial cells could be transplanted into the subarachnoid space, leading to formation of an epidermoid tumour.

Inappropriate positioning and poor anatomical knowledge are the primary reasons LPs fail, leading to increased procedure duration and morbidity. For children, the left lateral position, with hips fully flexed is recommended. This reverses the natural lumbar lordosis, opening the spaces between spinous processes and their adjacent laminae. A recent study suggests a sitting position with legs flexed at the hip should be considered for neonatal LP, as this maximises the interspinous space and causes less hypoxaemia.

Tuffier’s line, which joins the most superior aspect of both iliac crests, crosses the midline over the L4 spinous process as illustrated in figure 2. A space inferior to this is safe for performing LP (see figure 1). A wide aseptic field is mandatory.

Twenty drops of CSF equate to 1 mL. A minimum total sampling volume of 1.5–2 mL is routinely needed (table 1). Commonly, collection is in three universal containers plus a fluoride-containing tube for CSF glucose. Certain investigations require advanced preparation and liaison with the laboratory. CSF samples for neurotransmitters screen, for example, must be snap-frozen in dry ice or liquid nitrogen for immediate specimen transportation. Common LP technical issues and their remedy are presented in table 2.

**COMPlications**

LP is generally a safe procedure. Significant complications such as cranial neuropathies or meningitis are rare. A summary of individual complications is described in box 1.

**INDICATIONS FOR LP**

CSF analysis can be used to diagnose a variety of infective, inflammatory, metabolic and genetic nervous

CSF, cerebrospinal fluid.
system disorders. The National Institute for Health and Care Excellence guidelines recommend that all children with a suspicion of meningitis should undergo LP in the absence of contraindications. Important other clinical situations where LP is considered for diagnostic purposes are presented in tables 3 and 4.

LP and CSF removal may also aid in managing idiopathic intracranial hypertension. Therapeutic agents including antibiotics (eg, vancomycin) and chemotherapy (eg, methotrexate) can also be delivered via LP. Special training is required.

**CONTRAINDICATIONS TO LP**

Current National Institute for Health and Care Excellence guidelines state that CT scanning is unreliable to determine raised intracranial pressure in the assessment of patient’s suitability to undergo LP. Despite this mixed evidence, CT scanning is still recommended prior to LP if signs of raised intracranial pressure (ICP) are present, although it cannot exclude raised ICP definitively. Clinical examination should therefore guide appropriateness of LP. Box 2 summarises contraindications to LP.

**CLINICAL QUESTIONS**

In children undergoing LP, what preventive measures are most effective in reducing incidence of post-LP headache?

Post-LP headache is thought to arise due to persistent CSF leak from the puncture site. When the rate of leakage exceeds CSF production the volume of the cushion supporting the brain is reduced and the consequent gravitational forces on the innervated meningea result in pain. The headache is exacerbated by upright posture and typically lasts less than a week. Incidence is reported to be 32%.

Preventive measures include:

- Using smaller gauge needles; this is supported by adult practice studies, although a recent paediatric study found little corroborating evidence.
- Orientating the needle bevel parallel to the spine rather than inserting perpendicularly (7.9% headache rate vs 19.3%). Employing this technique separates rather than dissects longitudinal collagen dura mater fibres.
- Reinserting the stylet before withdrawing the needle (5% incidence vs 16% when not reinserted). Replacing the stylet is thought to prevent threading of arachnoid strands through the defect, which can prolong CSF leakage.
- Some studies have shown that use of a blunt (atraumatic) needle can reduce post LP headache. These needles are thought to separate the dural fibres and cause minimal tearing of the dura which results in less CSF leak.

It is often advised that post-LP headache can be avoided by lying flat afterwards, however a Cochrane review found little supporting evidence. Good hydration, analgesia and antiemetics have a supportive role, though the majority of post-LP headaches resolve without specific treatment. In prolonged or severe post-LP headache, epidural blood patching can be undertaken.

In children with suspected meningitis, can CSF lactate distinguish bacterial from viral causes?

In bacterial meningitis, CSF lactate is produced by bacterial anaerobic metabolism. It can therefore be useful in differentiating bacterial and viral meningitis, which may be difficult based on initial CSF results. In enterovirus meningitis, for example, CSF parameters can mimic those in bacterial meningitis. This results in unnecessary antibiotic administration in viral meningitis. One systematic review and meta-analysis of 25 studies examining CSF lactate in bacterial and viral meningitis concluded that CSF lactate is a good single differentiator, and is in fact better when compared with conventional markers such as CSF glucose and cell count.

Unlike CSF glucose, which requires a paired serum sample, CSF lactate does not. A CSF lactate level >3.5 mmol/L is indicative of bacterial meningitis.

</table>
Antibiotic treatment in many cases precedes LP; this often results in negative CSF bacterial cultures. A meta-analysis concluded that pretreatment with antibiotics reduces the clinical accuracy of CSF lactate. Diagnostic utility of a postantibiotic CSF lactate level is retained when considered in conjunction with clinical findings and laboratory tests.

In febrile infants under 3 months old with proven urinary tract infection, should LP routinely be performed? Urinary tract infection (UTI) affects one in six febrile infants younger than 30 days old. Up to 2% of infants less than 3 months with UTI have coexisting meningitis. The febrile infant under the age of 3 months can be difficult to assess, as pain and pyrexia can cause irritability, clouding the clinical picture. In these infants there is evidence suggesting LP should be performed, regardless of whether UTI is diagnosed.

In neonates with an elevated C reactive protein, should LP be routinely performed? Neonates often have blood taken at less than 24 h of age for a variety of reasons, including asymptomatic babies with maternal risk factors for infection. C reactive protein (CRP) in such babies is often elevated and practice on how to manage this often differs between hospitals and clinicians. CRP crosses the placenta in very low quantities, so an elevated CRP in a neonate always represents endogenous synthesis. However, an elevated CRP can be a physiological response to the stress of delivery, peaking at 13 mg/L on the 2nd day of life. CRP can also be raised in non-infection conditions such as intraventricular haemorrhage. Studies have suggested that serial CRP measurements have a higher sensitivity for sepsis than one-off measurements. One study considered babies who had full septic screens (including LP) for maternal risk factors. Of these babies 3423 were asymptomatic; none had meningitis. Of 11 cases of meningitis, all were symptomatic.

In paediatric idiopathic intracranial hypertension (IIH), does LP and removal of CSF reduce the symptoms? As previously mentioned, CSF is produced continuously. One study examined CSF production by measuring external ventricular drain losses in
Output increased logarithmically with age and body weight and output rates ranged from 0.1mL/h to 26.5 mL/h. Reducing intracranial pressure via LP by removing some CSF may provide temporary symptom relief which is usually short-lived. However, there is no evidence from research suggesting how much should be removed or even supporting this practice.

With continuous production of CSF, pressure can return to pretap concentrations within 1–2 h. Repeated taps are distressing, painful and run a theoretical risk of developing an intraspinal epidermoid tumour. Other treatments for IIH are therefore preferred.23

CNS, central nervous system; CSF, cerebrospinal fluid; LP, Lumbar puncture; WBC, white blood cells.
In traumatic LP, how is CSF pleocytosis diagnosed?

In healthy children and adults, a CSF white cell count of up to 5 cells/mm³ in the presence of up to 5 cells/mm³ of red cells is normal. When CSF is contaminated with blood, interpretation of the actual white cells count can be difficult. Very few studies have addressed this issue and the validity of the formulas currently recommended is debatable. Pragmatically, the ratio of the total white cell to the red blood cell counts on the peripheral full blood count done around the time of the LP can be used as a rough guide.

### Test your knowledge

1. Which of the following statements are true?
   A. Cerebrospinal fluid (CSF) protein levels are physiologically higher in neonates than in older children.
   B. A higher vertebral space should be used for lumbar puncture (LP) in neonates.
   C. EMLA is effective in neonates.
   D. A normal CT scan eliminates the risk of iatrogenic brain herniation.
   E. To reduce post-LP headaches, the needle bevel should face the patient’s top side on insertion.

2. For which of the following tests should the first drops of CSF be collected:
   A. Viral PCR.
   B. Lactate.
   C. Cells count.
   D. Neurotransmitters.
   E. Glucose.

3. Which of the following statements are true?
   A. Antibiotics should be withheld until LP has been performed in cases of suspected bacterial meningitis to obtain sensitivities.
   B. CSF lactate is not diagnostically useful without a paired serum sample.
   C. An opening pressure of 29 cm H₂O in a normal weight child is considered high.
   D. CT head scan should be requested prior to LP for a patient with a GCS of 8.
   E. A CSF result of normal cell count and high protein is consistent with a diagnosis of Guillain-Barré syndrome.

4. A lumbar puncture is helpful in the following clinical situations:
   A. A ventilated preterm baby with a rising C reactive protein and a negative blood culture.
   B. A 7 year-old with acute onset of unsteady gait and weak lower limbs.
   C. A 4 year-old with a temperature of 39°C and decorticate posturing.
   D. A 6 week-old boy with fever and a positive urine culture.
   E. A 10 day-old with intractable seizures and a ‘burst-suppression’ background on EEG.

5. The following are true in the interpretation of CSF results:
   A. CSF lactate is helpful in differentiating between viral and bacterial meningitis.
   B. Increased CSF protein is indicative of a neuroinflammatory disorder.
   C. CSF oligoclonal bands are present in a wide range of paediatric neurological disorders.
   D. Blood glucose is not usually required in interpreting CSF values.
   E. High CSF glucose is consistent with glucose transporter type 1 deficiency syndrome.

Answers are at the end of the references.
guide. If the ratio in the CSF is higher, then CSF pleocytosis is likely to be present.

TOPICS FOR FURTHER RESEARCH
For the majority of diagnostic procedures in modern clinical practice, radiological guidance is used to maximise the safety and efficacy of the procedure. However, the vast majority of LPs occur ‘blind’, with anatomical landmarks used to identify the puncture site. There is some evidence from the adult literature to suggest ultrasound guidance is beneficial, especially for difficult procedures. Small trials have suggested higher success rate when ultrasound guidance is used routinely. There is limited paediatric evidence, with the majority of research looking at using ultrasound to assess spinal anatomy, and not to guide the procedure itself. A few small trials suggest it is feasible, however larger randomised trials are needed.
